Quicksort Algorithm

In this tutorial, you will learn about the quick sort algorithm and its implementation in Python, Java, C, and C++.

Quicksort is a [sorting algorithm](#) based on the **divide and conquer approach** where

1. An array is divided into subarrays by selecting a **pivot element** (element selected from the array).

While dividing the array, the pivot element should be positioned in such a way that elements less than pivot are kept on the left side and elements greater than pivot are on the right side of the pivot.

2. The left and right subarrays are also divided using the same approach. This process continues until each subarray contains a single element.
3. At this point, elements are already sorted. Finally, elements are combined to form a sorted array.

Working of Quicksort Algorithm

1. Select the Pivot Element

There are different variations of quicksort where the pivot element is selected from different positions. Here, we will be selecting the rightmost element of the array as the pivot element.

8 7 6 1 0 9 2

Select a pivot element

2. Rearrange the Array

Now the elements of the array are rearranged so that elements that are smaller than the pivot are put on the left and the elements greater than the pivot are put on the right.

1 0 2 8 7 9 6

Put all the smaller elements on the left and greater on the right of pivot element

Here's how we rearrange the array:

1. A pointer is fixed at the pivot element. The pivot element is compared with the elements beginning from the first index.

8 7 6 1 0 9 2
↑ comparison ↑ pointer

Comparison of pivot element with element beginning from the first index

2. If the element is greater than the pivot element, a second pointer is set for that element.

8 7 6 1 0 9 2
↑ second pointer ↑

If the element is greater than the pivot element, a second pointer is set for that element.

3. Now, pivot is compared with other elements. If an element smaller than the pivot element is reached, the smaller element is swapped with the greater element found earlier.

8 7 6 1 0 9 2
↑ ↑
8 7 6 1 0 9 2
↑ ↑
1 7 6 8 0 9 2

- Again, the process is repeated to set the next greater element as the second pointer. And, swap it with another smaller element.

- The process goes on until the second last element is reached.

- Finally, the pivot element is swapped with the second pointer.

3. Divide Subarrays

Pivot elements are again chosen for the left and the right sub-parts separately. And, **step 2** is repeated.

The subarrays are divided until each subarray is formed of a single element. At this point, the array is already sorted.

Quick Sort Algorithm

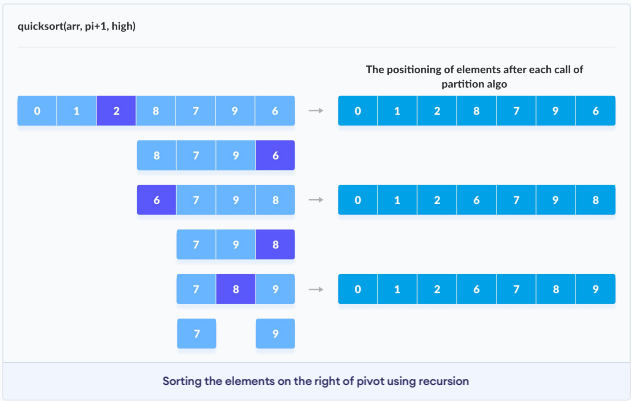

```
quickSort(array, leftmostIndex, rightmostIndex)
if (leftmostIndex < rightmostIndex)
  pivotIndex <- partition(array, leftmostIndex, rightmostIndex)
  quickSort(array, leftmostIndex, pivotIndex - 1)
  quickSort(array, pivotIndex, rightmostIndex)

partition(array, leftmostIndex, rightmostIndex)
set rightmostIndex as pivotIndex
storeIndex <- leftmostIndex - 1
for i <- leftmostIndex + 1 to rightmostIndex
  if element[i] < pivotElement
    swap element[i] and element[storeIndex]
    storeIndex++
  swap pivotElement and element[storeIndex+1]
return storeIndex + 1
```

Visual Illustration of Quicksort Algorithm

You can understand the working of quicksort algorithm with the help of the illustrations below.

Quicksort Code in Python, Java, and C/C++

```
Python Java C C++

// Quick sort in Java
import java.util.Arrays;

class Quicksort {

    // method to find the partition position
    static int partition(int array[], int low, int high) {

        // choose the rightmost element as pivot
        int pivot = array[high];

        // pointer for greater element
        int i = (low - 1);

        // traverse through all elements
        // compare each element with pivot
        for (int j = low; j < high; j++) {
            if (array[j] <= pivot) {

                // if element smaller than pivot is found
                // swap it with the greater element pointed by i
                i++;

                // swapping element at i with element at j
                int temp = array[i];
                array[i] = array[j];
                array[j] = temp;
            }
        }

        // swap the pivot element with the element at i
        int temp = array[i];
        array[i] = array[high];
        array[high] = temp;

        return i;
    }

    // method to sort the array
    static void sort(int array[], int low, int high) {
        if (low < high) {
            int pi = partition(array, low, high);
            sort(array, low, pi - 1);
            sort(array, pi + 1, high);
        }
    }
}
```

Quicksort Complexity

Time Complexity	
Best	$O(n \log n)$
Worst	$O(n^2)$
Average	$O(n \log n)$
Space Complexity	
$O(\log n)$	
Stability	
No	

1. Time Complexities

• Worst Case Complexity [Big-O]: $O(n^2)$

It occurs when the pivot element picked is either the greatest or the smallest element.

This condition leads to the case in which the pivot element lies in an extreme end of the sorted array. One sub-array is always empty and another sub-array contains $n - 1$ elements. Thus, quicksort is called only on this sub-array.

However, the quicksort algorithm has better performance for scattered pivots.

• Best Case Complexity [Big-omega]: $O(n \log n)$

It occurs when the pivot element is always the middle element or near to the middle element.

• Average Case Complexity [Big-theta]: $O(n \log n)$

It occurs when the above conditions do not occur.

2. Space Complexity

The space complexity for quicksort is $O(\log n)$.

Quicksort Applications

Quicksort algorithm is used when

- the programming language is good for recursion
- time complexity matters
- space complexity matters
